

A toy model of Polyakov duality

Abstract

Polyakov has conjectured that Yang–Mills theory should be equivalent to a noncritical string theory. I pointed out, based on the work of Marchesini, Ishibashi, Kawai and collaborators, and Jevicki and Rodrigues, that the loop operator of the Yang–Mills theory is the temporal gauge string field theory Hamiltonian of a noncritical string theory. In the present note I explicitly show how this works for the one–plaquette model, providing a consistent direct string interpretation of the unitary matrix model for the first time.

The naturality of a string interpretation of Yang–Mills theory was first appreciated by Mandelstam [1], and has been elaborated upon with significant insights by many others [2]. The Wilson loop observables of gauge theories satisfy dynamical Schwinger–Dyson equations that have precise geometric interpretations [3]. These loop equations simplify considerably in the limit $N \uparrow \infty$ where N is the rank of the gauge group. This is also natural for the string interpretation following ‘t Hooft’s study of the large N limit of gauge theories, since this is the limit when string loop contributions to amplitudes are suppressed. Thus Wilson loop expectation values in the large N gauge theory satisfy classical equations. The loop equation appears also as the saddle–point equation in the collective field theory setup of Jevicki and Sakita [4].

Strings do not interact in this limit—yet the loop equation has terms corresponding to the splitting of strings, and terms that annihilate strings. This, of course, is completely consistent, but not entirely obvious to the string theorist steeped in the lore of critical string theories in conformal gauge. Indeed, the simplest physical interpretation of the loop equation and its meaning in a string theory equivalent to the Yang–Mills theory is obtained by combining [5] two beautiful results. The first of these is the observation of Marchesini [6] that the Fokker–Planck Hamiltonian that arises in Parisi–Wustochastic quantization [7] is precisely the loop operator, *i.e.* the operator H such that

$$\langle H \prod_i W(C_i) \rangle = 0 \quad (1)$$

are the Schwinger–Dyson loop equations. The second result is that of Jevicki and Rodrigues [8]: the temporal gauge noncritical string field theory Hamiltonian found in the work of Ishibashi, Kawai and collaborators [9] is the Fokker–Planck Hamiltonian of the matrix model representation of the noncritical string theory. (For earlier relevant work see [11,12].) Combining these results, I found that the loop operator of the Yang–Mills theory

can be interpreted as the exact string field theory Hamiltonian of a noncritical string theory, *provided* a crucial consistency condition is satisfied: the loops must be defined in a manner that preserves the zig–zag symmetry emphasized by Polyakov [13]. The string theory defined by the loop operator is valid at arbitrary N .

Now loop equations are notorious for requiring careful regularization [14], so one must make such formal statements precise with well–defined operators. Fortunately, since one is automatically in the framework of stochastic quantization [7,15] there is in fact a continuum regularization available [16]. I derive in detail the noncritical string theories one obtains in this manner in [26], but the aim of the present paper is to present a simple toy model in which all the features mentioned in the previous paragraph are as transparent as can be. In the process, one finds a resolution for the (decidedly minor) puzzle of a string interpretation of the unitary matrix model to which I now turn.

The depth of the large N limit is nowhere more apparent than in the model of one Hermitian matrix first solved by Brézin, Itzykson, Parisi and Zuber [17]. The analogue of their model for gauge theories is the one–plaquette model solved by Gross and Witten [18]. This model is defined by a Wilson lattice gauge theory action but involving only one plaquette:

$$\mathcal{Z} = \int dU \exp \left(\beta \text{tr} \left[V(U) + V(U^\dagger) \right] \right) \quad (2)$$

where U is a unitary matrix in $U(N)$. This model is solved as follows: U can be diagonalized since the action and the measure are invariant under $U \rightarrow \eta U \eta^\dagger$. There is a Jacobian that appears in this process so we end up with

$$\mathcal{Z} \propto \int \prod d\theta_i |\Delta(\theta_i)|^2 \exp \left(\beta \sum \left[V(e^{i\theta_j}) + V(e^{-i\theta_j}) \right] \right) \quad (3)$$

where Δ is the Vandermonde determinant $\prod_{j>i} (e^{i\theta_i} - e^{i\theta_j})$. This integral can be evaluated by saddlepoints in the large N limit when $N/\beta \equiv \lambda$ is held fixed. Gross and Witten [18] found a third–order phase transition in this model. This transition occurs when the coupling λ is strong enough that the eigenvalue distribution has support on the entire unit circle in the complex plane.

The double–scaling limit [19] solves the Hermitian matrix model [17] to all orders in $1/N$, and the random surface interpretation dual to the Feynman diagrams of the perturbative evaluation [20] of the model leads to a connection with quantum gravity in two dimensions [21]. The double–scaling limit can also be used to solve the one–plaquette model in a monkey–see, monkey–do [22] fashion but there is no convincing random surface interpretation of this model. The best attempt is presented in [23], but this is not directly on the basis of observables in the matrix integral, but rather in terms of transformations of integrable hierarchy equations that arise in these models.

This lack of an interpretation (see, for example, [24]) is surprising. In fact, it seems to be entirely due to an elision in the literature of the fact that this model is a gauge theory on a single plaquette. The natural observables in such a gauge theory are $\text{Tr} U^n \equiv \text{tr} U^n / N$, where n takes positive or negative integer values. These are just Wilson loops corresponding to paths wound around the plaquette n times, *i.e.* in terms of the discussion at the beginning of this paper, *strings* wound around the plaquette.

Let us derive the Schwinger–Dyson equations for this model. By the right translation invariance of the unitary group Haar measure, we have

$$\int dU e^{\beta \text{tr}[V(U)+V(U^\dagger)]} \text{Tr}(T_\alpha U^n) = \int dU e^{\beta \text{tr}[V(Ue^H)+V(e^{-H}U^\dagger)]} \text{Tr}(T_\alpha (Ue^H)^n) \quad (4)$$

where T_α is a normalized anti-Hermitian matrix and $H \equiv \sum_\beta H^\beta T_\beta$ is an arbitrary anti-Hermitian matrix expanded in terms of the N^2 basis matrices T_β . Using the identities

$$\sum_\alpha \text{tr} A T_\alpha B T_\alpha = -\text{tr} A \text{tr} B, \quad \sum_\alpha \text{tr} A T_\alpha \text{tr} B T_\alpha = -\text{tr} A B \quad (5)$$

after differentiating with respect to H^α and summing over α , we find [25] (in the large N limit, for the simplest case $V(U) = U$)

$$\frac{1}{\lambda} (z_{n+1} - z_{n-1}) + \sum_{p=1}^n z_p z_{n-p} = 0, \quad n \geq 1. \quad (6)$$

Here we have defined $\langle \text{Tr} U^n \rangle \equiv z_n$, so in particular $z_0 = 1$. This eq. 6 is precisely the loop equation [3] in this model. This recursion relation can be used to determine all the observables z_n as a function of λ , but it should be noted that this equation does not fix z_1 . For general V , we would need to evaluate $2d - 1$ z_i independently where d is the degree of the polynomial V . Rodrigues [25] studied eq. 6 in detail. In the present case, we shall see that it is possible to fix z_1 by finding the Fokker–Planck Hamiltonian underlying eq. 6, and demanding that the amplitudes computed from this Hamiltonian reproduce eq. 6.

The loop operator derived from eq. 6 is just (for $N = \infty$)

$$H_\infty \equiv T(\lambda) a_1 + \sum_{n>0} n \left[\frac{1}{\lambda} (a_{n+1}^\dagger - (1 - \delta_{n,1}) a_{n-1}^\dagger) + a_n^\dagger + \sum_{p=1}^{n-1} a_p^\dagger a_{n-p}^\dagger \right] a_n + n < 0 \text{ terms} \quad (7)$$

where I have introduced creation and annihilation operators $[a_n, a_m^\dagger] = \delta_{n,m}$, for $|n| > 0$, which create and annihilate strings of winding number n . In the absence of string merging, strings with positive or negative winding number do not interact.

The string propagates in stochastic time, identified on the basis of [9,8,10] with Liouville time in a noncritical string theory. Physical correlation functions are obtained, as standard in stochastic quantization [7,15], via

$$\lim_{\tau \uparrow \infty} \langle 0 | e^{-\tau H_\infty} \prod_i a_i^\dagger | 0 \rangle \equiv \prod_i z_i \quad (8)$$

in the large N factorization since the strings cannot merge in this limit. We need to fix $T(\lambda)$. We require therefore

$$\lim_{\tau \uparrow \infty} \langle 0 | e^{-\tau H_\infty} a_1^\dagger | 0 \rangle = z_1. \quad (9)$$

Following [10], the existence of the large τ limit and $H_\infty | 0 \rangle = 0$ implies

$$\lim_{\tau \uparrow \infty} \langle 0 | e^{-\tau H_\infty} [H_\infty, a_1^\dagger] | 0 \rangle = 0. \quad (10)$$

Since a string of winding number 1 cannot split, eq. 10 gives

$$T + z_1 + \frac{1}{\lambda} z_2 = 0. \quad (11)$$

Comparing eq. 11 to eq. 6 we find $T = -1/\lambda$. A simpler way to write H_∞ is therefore

$$H_\infty = \sum_{n>0} n \left[\frac{1}{\lambda} (a_{n+1}^\dagger - (1 - \delta_{n,1}) a_{n-1}^\dagger - \delta_{n,1}) + a_n^\dagger + \sum_{p=1}^{n-1} a_p^\dagger a_{n-p}^\dagger \right] a_n + n < 0 \text{ terms} \quad (12)$$

which could have been anticipated. Consider the physics of the two limiting values of λ . For small λ the kinetic term dominates and the string grows or shrinks but does not split very often—the dominant splitting is into one big string and one small string that is then annihilated. For large λ the string splits all the time, and the tadpole is small as well. It is easy to see that in this limit $z_1 = 0$, which is of course obvious from $\mathcal{Z}$. In the eigenvalue picture, the eigenvalue distribution is concentrated in a sector on the circle in the weak coupling (λ small) limit whereas it spreads over the whole circle at strong coupling. Presumably the phase transition occurs when string splitting is compensated by string growth so that the propagation of the string has a self-similar character.

Having found T in this model, we can evaluate z_1 just using H_∞ in eq. 9 as claimed. In this sense, the one-plaquette model is complete since we used eq. 6 to derive the form of H_∞ anyway. (It is of course possible to evaluate z_1 independently. First of all, notice that on account of the symmetry of the measure and the action under inverting U , we have $z_i = z_{-i}$. Next, we obviously have

$$z_1 + z_{-1} = \frac{1}{N} \frac{\partial}{\partial \beta} \ln \mathcal{Z} \quad (13)$$

and $\mathcal{Z}$ is easily evaluated following [18].)

Consider now finite values of N . Correlations no longer factorize so we consider more general Schwinger–Dyson equations:

$$\sum_\alpha \frac{\partial}{\partial H^\alpha} \int dU e^{\beta \text{tr}[V(Ue^H) + V(e^{-H}U^\dagger)]} \sum_{j=1}^m n_j \text{Tr}(T_\alpha (Ue^H)^{n_j}) \prod_{i \neq j} \text{Tr}((Ue^H)^{n_i}) \Big|_{H=0} = 0 \quad (14)$$

n_i need no longer be all positive or all negative, since we must allow for strings that wind in either direction. We now find a new term, involving the joining of strings:

$$\left\langle \sum_j (H_\infty W(n_j)) \prod_{i \neq j} W(n_i) + \frac{1}{N^2} \sum_j \sum_{i \neq j} n_i n_j W(n_i + n_j) \prod_{k \neq i, j} W(n_k) \right\rangle = 0 \quad (15)$$

where we have defined $\text{Tr} U^{n_i} \equiv W(n_i)$. The extra factor of N^{-2} arises because the traces in eq. 5 are not normalized. While we can no longer write a recursion relation for the single operator expectation values z_i , we can write down the finite N Hamiltonian from eq. 15:

$$H_N = H_\infty + \frac{1}{N^2} \sum_{i, j} i j a_{i+j}^\dagger a_i a_j, \quad (16)$$

implicitly replacing $a_0^\dagger \rightarrow 1$. A striking difference between this Hamiltonian (eq. 16) and the Hamiltonian in [10] is that here we have strings with positive and negative windings, whereas in [10] the string length alone is the string field parameter. Recall that in the case of orthogonal polynomials on a circle it is a similar appearance of negative and positive powers of $z \equiv e^{i\theta}$ that results in distinct recursion relations compared to orthogonal polynomials on the real line. It is important to note here that the string joining term is to be treated in perturbation theory for consistency.

Given the Hamiltonian H_N , we can write down a string field theory. Written in holomorphic coördinates, the functional integral for the stochastic time evolution is

$$U(a_i^*, a_j; \tau_f, \tau_i) = \int \prod_{n, \tau} \frac{da_n^* da_n}{2\pi i} e^{\frac{1}{2} \sum_n [a_n^*(\tau_f) a_n(\tau_f) + a_n^*(\tau_i) a_n(\tau_i)]} e^{-\int_{\tau_i}^{\tau_f} L_{FP}} \quad (17)$$

with the Lagrangian $L_{FP} = (1/2i) \sum_{n \neq 0} (\dot{a}_n^* a_n - a_n^* \dot{a}_n) - H_{FP}$ and

$$H_{FP} \equiv \sum n \left[\frac{1}{\lambda} (a_{n+1}^* - a_{n-1}^*) + a_n^* + \sum_{p=1}^{n-1} a_p^* a_{n-p}^* \right] a_n + n < 0 \text{ terms} + \frac{1}{N^2} \sum_{i,j} i j a_{i+j}^* a_i a_j. \quad (18)$$

(Recall $a_0^* \equiv 1$.) For our purposes, we require vacuum boundary conditions at $\tau_f = \infty$, and the specified Wilson loops in the correlation function at $\tau_i = 0$. In nontrivial models [26] the regularization needed can only be implemented at the level of the loop operator, not in the functional integral derived from the loop operator [16]. Another striking feature of the functional integral, not perhaps most obvious in eq. 17, is the appearance of supersymmetry in the string field theory as usual in stochastic quantization [27,15].

There is much more that one can derive explicitly in these models especially taking finite N corrections into account. The explicit solution found in [22] can be used as a check on this formalism. The main point of this paper however is that there is a string interpretation of the simplest Yang–Mills theory, the one–plaquette model. This string interpretation is precisely as stated in [5], as a noncritical string field theory in temporal gauge, and therefore is a concrete example of Polyakov’s conjecture [13]. The zig–zag symmetry is of course built into the formalism here, but needs much more work to maintain in nontrivial models [26].

Turning to the interpretation of [23], it could be that the mapping between the unitary matrix model and models of closed and open strings found in [23] is hiding some deeper duality between closed string and open and closed string theories. The Polyakov duality between Yang–Mills theory and a *noncritical* closed string theory is what has been demonstrated here in a toy model.

I am grateful to L. Yaffe for asking the question this note answers, and especially to G. Lifschytz for sharing his insights. I acknowledge a helpful conversation with I. Klebanov and helpful comments by A. Polyakov. This work was supported in part by NSF grant PHY-9802484.
